GETTING STARTED

1 License 3

PHPCoord is a PHP library to aid in handling coordinates. It can convert coordinates for a point from one system to another and also calculate distance between points.

6982 different coordinate systems are supported, covering the entire globe. Common systems supported include:

- WGS84 (GPS)
- OSGB36 (Great Britain)
- NAD27 and NAD83 (North America)
- UTM (Universal Transverse Mercator)
- ED50 and ETRS89 (Europe)
- GDA94 and GDA2020 (Australia)
- NZGD49 and NZGD2000 (New Zealand)

PHPCoord code is licensed under the MIT license. It uses the EPSG dataset which is made available under the EPSG license. See license.txt for full details.

1.1 Installation

The recommended way to install PHPCoord is to use Composer. From the command line simply execute the following to add `php-coord/php-coord` to your project's `composer.json` file. Composer will automatically take care of downloading the source and configuring an autoloader:

```
composer require php-coord/php-coord
```

For *increased accuracy* of conversions, you may wish to install one or more optional add-on datapacks:

- `php-coord/datapack-africa`
- `php-coord/datapack-antarctic`
- `php-coord/datapack-arctic`
- `php-coord/datapack-asia`
- `php-coord/datapack-europe`
- `php-coord/datapack-northamerica`
- `php-coord/datapack-oceania`
- `php-coord/datapack-southamerica`

The code for the core package and the datapacks is also available to download from GitHub

1.1.1 Requirements

PHPCoord v5 is compatible with PHP 8.0+

1.2 A quick primer on geodesy concepts

Coordinates are hard. If they were easy, you wouldn't have needed to find this library. The below is intended as a quick guide to the basic concepts involved in geodesy (the science of measuring the Earth's shape) intended to allow you to more fully understand the terminology used within the library. It is **not** necessary to read or memorise this documentation section to use the library, it's just here for educational purposes.

1.2.1 What is a coordinate?

X marks the spot

A coordinate (or set of coordinates) is a reference to a particular point on the Earth, or in the near vicinity of it (e.g. the location of an aeroplane flying from A to B can still be identified by coordinates). Points are identified by a set of distances (and direction) from a known starting point. A simple example would be a pirate map saying that the buried treasure is 200 paces south-east of the old palm tree. Modern mapping doesn't measure distances from random trees, but the principle is the same - pick a starting point and measure out distance(s) in the specified direction(s).

But how can someone find that starting point to start counting from? How does a treasure hunter find the right palm tree (or even the right town?). You could measure out as a set of distances from a different tree, but that leads to circularity very quickly. The answer is to special-case the starting point and to define it differently in terms of the physical characteristics of the Earth. Pirate maps have pictures of coves and other local landmarks for this purpose, serious mapping uses *science*.

Datums

Technically, a datum is a set of described measurements to be performed on the Earth. The results of the measurements give the known starting point. Sometimes, when repeating what in theory are the same measurements different results are obtained - this can be because of simple error, or can also be because newer measurements are able to use more precise measuring techniques. Where this occurs, each set of measurements is termed a new *realisation* of the same datum.

Most datums have only ever had 1 realisation made, and therefore the word datum usually refers to the results rather than the method.

There are two types of datum: *geodetic* and *vertical*. The next few sections relate to the geodetic kind, vertical datums are covered further below.

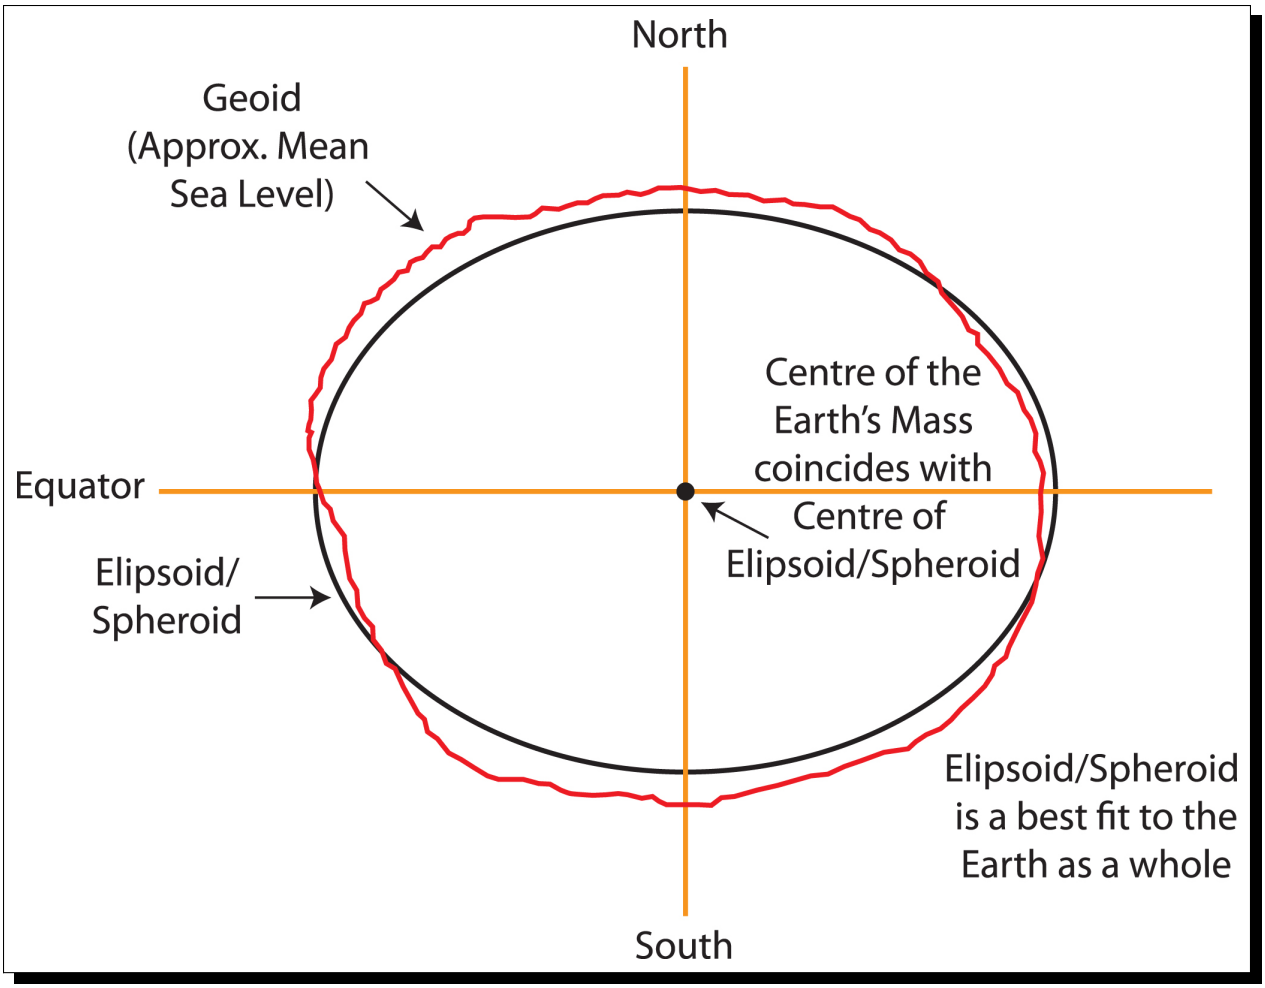
Ellipsoids

Before dividing the world into latitudes and longitudes or whatever other system is used, the first thing that needs to be agreed on is the shape and size of the planet. Otherwise, my latitude/longitude grid[1] and your latitude/longitude grid won't match up.

Although the Earth is normally pictured as spherical, it is actually very slightly wider at the equator than between the north and south poles making it more elliptical in nature. A 3D ellipse is called an *ellipsoid*. The Earth is not a perfect ellipsoid, it's more lumpy and bumpy than that but for the purposes of actually being able to perform any calculations at all, slight distortions from reality are usually accepted.

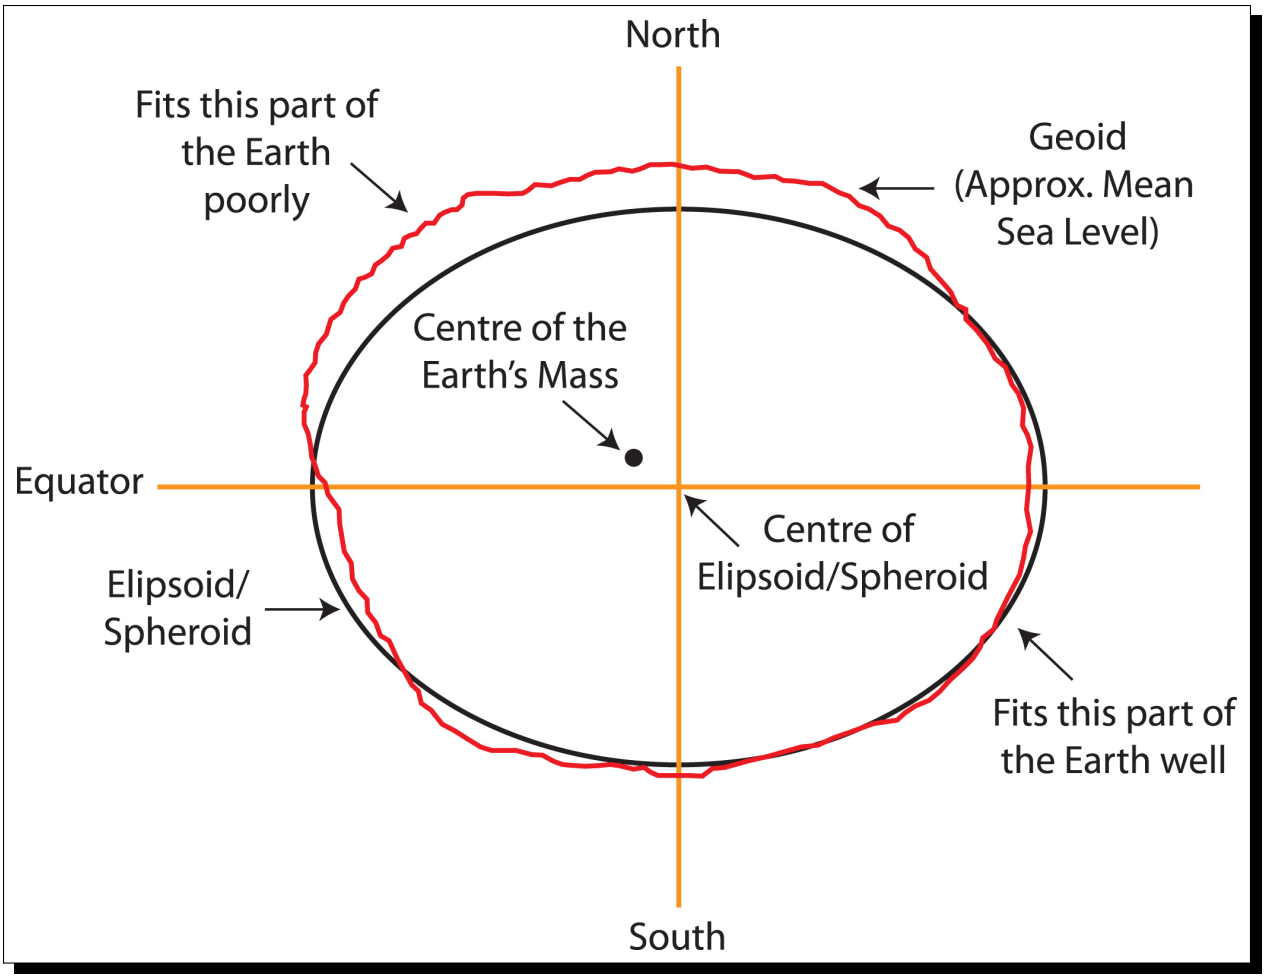
A global ellipsoid

[1] Technically called a graticule, but nobody knows that word



However, historically there has not been a unified view of what those distortions should be. Nowadays, many (most?) coordinates are generated by devices making use of GPS and other such similar global satellite systems. By their very nature, needing to work worldwide, a great deal of effort was made to pick an ellipsoid that minimised distortions on a global basis. Even with that effort, new measurements and refinements from improving satellite technologies resulted in evolution of the scientific consensus on the dimensions of the true "best-fit" ellipsoid several times and therefore different mapping systems make use of different ellipsoids.

A regional ellipsoid



Before satellite positioning though, mapping was usually done by surveying and on a much more regional basis. It was therefore commonplace for such mapping to purposefully make use of an ellipsoid that was a closer match to the actual Earth surface in the area of interest, with the greater resulting mismatch from reality in parts of the globe that weren't going to feature on the map being perfectly acceptable.

Thus, one of the most common reasons for needing to convert coordinates is that the source system and target system are based on entirely different ellipsoids.

Axes

Since we live in a 3D world, for full accuracy it is necessary to use 3 axes to describe the distance and direction of our point of interest from the known starting point (which I'll call the origin going forward). For simplicity, we'll ignore height for now and assume all points are at surface level. Thus, 2 axes are needed. Keeping in line with the philosophy of using physical attributes of the Earth to define things, a consistent practice of using North-South and East-West for these axes has been used since the time of the Ancient Greeks.

North-South

For measurements along the north-south axis, the easiest thing to do is to define 0 to be the halfway point between the two poles. Thus, in a latitude/longitude based system 0° latitude is the line around the equator. All geodetic datums use this definition.

East-West

There is no East Pole or West Pole, so unfortunately the same type of physical definition cannot be used to pick where to place the east-west axis. There are actually an infinite number of possible choices, the decision is essentially arbitrary. Because of this, the choice of where to draw the 0 line must be recorded as part of the datum definition. The chosen location is called the *Prime Meridian*.

The Ancient Greeks picked the westernmost point of the known world to be their Prime Meridian, which came with the helpful property for them that all longitudes were positive numbers. As map-making became more scientific in nature in the 18th century, many countries started using meridians that passed through their capital cities - e.g. French maps used Paris, German maps used Berlin. This was probably at least partially for reasons of national pride but also since longitude was more difficult to determine in those days, having the known 0 reference point inside the territory will have had practical benefits to those doing the measuring.

Eventually, international agreement was reached to standardise on a single meridian worldwide, that choice being the one passing through the Royal Observatory, Greenwich.

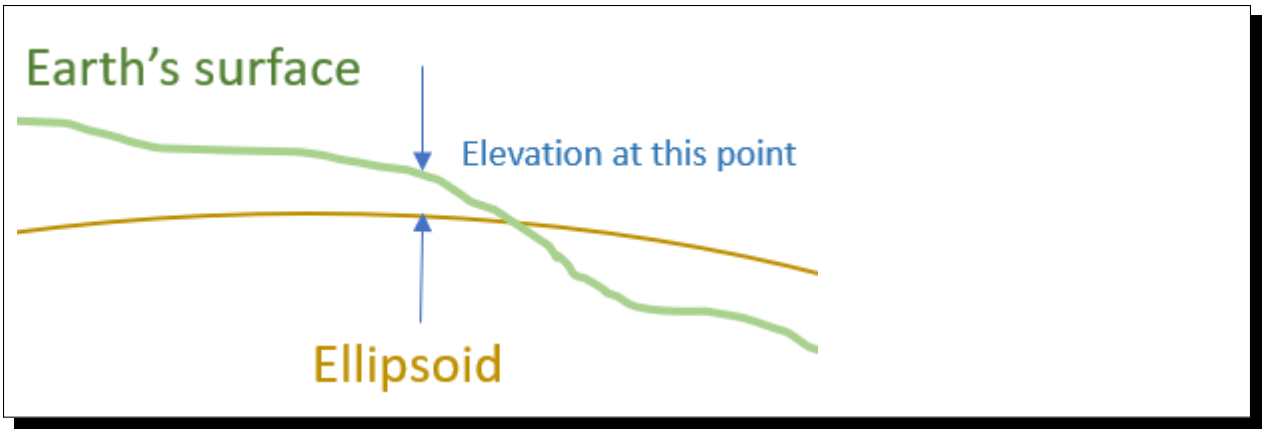
Note: From the above, you may have realised that the origin point for north-south measurements (the equator), and the origin point for east-west (typically Greenwich) can be several thousand miles away from each other on completely different continents. This seems very complicated compared to the pirate map. Wouldn't it be simpler to simply pick the Royal Observatory as (0,0) and measure everything from that single point?

The answer is that to measure distances in the way pirate maps do it requires either direct access to the origin point to measure out directly from (it had better be close!) or a network of other points with known coordinates that you can measure indirectly from. In fact, surveying makes heavy use of this very principle even today. However, it is not always practicable to find such points with known coordinates to measure from - for instance in remote areas, or for ships at sea.

With the right equipment and training, it is however possible to make standalone measurements of latitude and longitude from anywhere on the planet. This is useful.

Ellipsoid height

The ellipsoid vs reality



Height is a concept that intuitively sounds very simple, but gets complicated very quickly (there is a section below that expands on this). For now however, remember that the ellipsoidal model of the Earth is just an approximation, which means this imaginary ellipsoid sometimes passes underneath "true" ground level, and sometimes passes above it. Thus, although "height" above or below the ellipsoid can theoretically be calculated and used to accurately place a point within a 3D space, it is of very limited practical use on the ground since the ellipsoid cannot actually be seen.

Coordinate reference systems (CRSs)

A Coordinate Reference System, is the combination of a *Datum* and a *Coordinate System* which is the particular set of axes being used to measure distances on.

It is very important to know the set of axes being used, because otherwise numbers are very prone to misintepretation - for example `42.0669, 11.8128` would be near Rome if the order is (latitude, longitude), but near Djibouti if the order is (longitude, latitude). That's assuming the measurement is in decimal degrees, and not some other unit such as gradians.

Most map projections use metres, but some use feet. Many use Eastings and Northings, but some are Northings and Eastings. Some are Southings and Westings. Some are just X and Y, but some use X to mean East and others use it to mean North. Some write the X coordinate first, some write the Y coordinate first. Just about every permutation of meaning and order exists.

> **Warning:** When taking in coordinates from an external system, always, always, always check the **unit**, and the **order** of the numbers if they are not already clearly labelled.

Geographic

Geographic coordinates are those that use latitude/longitude (and optionally ellipsoid height).

Earth-centered (geocentric)

Longitudes are not of constant width, each degree covers a significantly wider area near the equator than near the poles. This means any calculations involving them involves **a lot** of trigonometry. For this reason, coordinates are sometimes expressed as 3 distances (3 axes…) from the centre of the Earth instead, with the axes angled so as to respect the datum definition (one runs through the poles, one runs through the line of prime meridian). GPS signals use this system, although the result is usually converted to latitude and longitude for display.

Projection (maps)

The 3D model describing the shape of the Earth is great from a scientific point of view, but comes with severe drawbacks for everyday use. A pirate has not, and never will, carry around a pocket globe. It's just not practicable.

Like all humans, they prefer flat, foldable (portable!) maps.

Unpeeling the globe

Apart from portability, one of the other main benefits of flat maps is that unlike latitudes and longitudes, map grids have a fixed scale which makes measuring distances between points in everyday units such as metres nice and easy.

Unfortunately, there is no method of drawing out what is inherently a 3D shape onto a 2D surface whilst retaining full fidelity. There are ways of maintaining accuracy of shape, but they involve distorting size. There are also ways to maintain accurate size, but that involves some distortion of shape. Many mapmaking techniques aim for a compromise between the two. Usually, the technique (called a projection) is chosen so that distortions are only noticeable at very large scale e.g. maps that try to show entire countries at once. A well-produced map of e.g. a single town will not show such effects.

Complicating things further, some projection methods work really well for tall, skinny areas (think Italy) but work much less well on a more square-like areas (think France) so there are many methods in use worldwide.

Note: All projected coordinate systems are based upon an existing geographic or geocentric system, and therefore

have a datum and ellipsoid inside their formal definitions.

Vertical

Because ellipsoidal heights are impractical to measure from the ground, it is common practice to ignore them completely and measure heights using a completely different system (you might have heard of a height being referred to as "above sea level"). A vertical coordinate system is by its nature 1 dimensional.

Compound

A compound coordinate, is simply the combination of a 2D geographic or projected coordinate and 1D vertical coordinate. Such a system is called 2D+1D to distinguish it from an actual 3D system such as a geocentric coordinate or a geographic coordinate that includes an ellipsoid height.

Heights

What is a height? In everyday usage, a height would be described as a distance above (or potentially below) a reference point. Easy. There are just 2 problems with that definition:

1) As discussed previously, defining something in terms of a real, physical point can produce difficulty in making measurements since it is not possible to determine the coordinates of your current location without having the known coordinates of a different point within sight
2) We also covered that a coordinate is a distance *and direction* from another point. As it turns out, "above" can be a complicated concept.

Before satellite positioning existed the first problem was ignored by mapmakers (or rather the practical difficulties were accepted as necessary). Heights were measured off a fixed point because there simply wasn't an alternative. In the UK mainland the basis for zero height is mean sea level at Newlyn in Cornwall as read off the tide gauge a hundred years ago and a marker was placed to use as physical reference. For Northern Ireland, using a reference point in Cornwall is physically impossible and thus a different sea-level based reference point was established in Belfast.

Other islands around the UK coast also have their own 0m markers, and countries worldwide all use similar systems, for instance the US and Canada use a system based upon the water in the Great Lakes and France has historically measured heights from a spot near Marseille.

True Story

In 2015, the primary marker for the American Samoa Vertical Datum on the island of Tutuila was destroyed in an earthquake. Other secondary markers with derived/calculated heights were present on the island, but the earthquake meant that they had moved too much to be considered reliable indicators of their claimed position and therefore could not safely be used to back-calculate where the original 0m height line was.

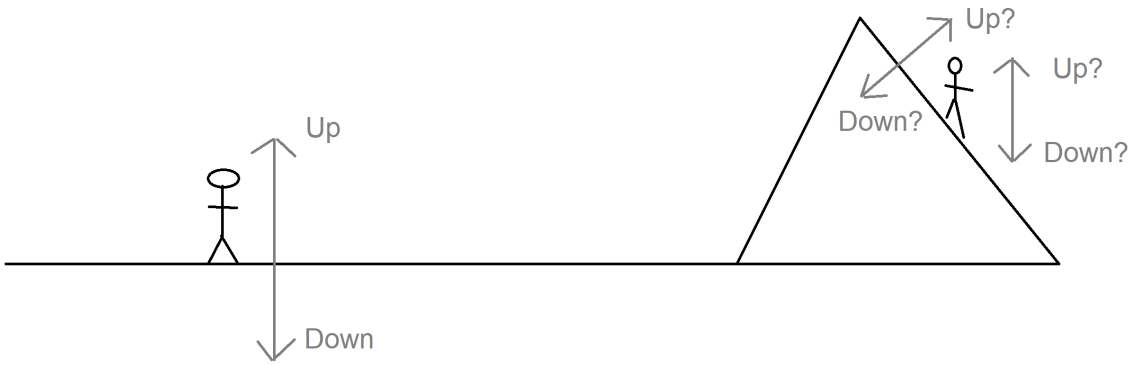
As a result, the US was forced to declare the datum as obsolete and today when height information is needed fresh surveys have to be made based on a new 0m origin marker that has no relation to the previous origin.

Caution: Despite all being based on sea level, the 0m Newlyn marker, the 0m Belfast marker, the 0m Marseille marker and any/all other markers in different countries have *absolutely nothing in common with each other and are not interchangeable*. They were created at different dates, and even if they had all been created on the same day, sea levels at different points on the globe are not equal.

Which way up?

The other problem is the "direction" of height. In order to work out the relative height of an arbitrary point compared to the reference marker a surveyor needs to know what direction to make their measurements.

Flat Earther problems

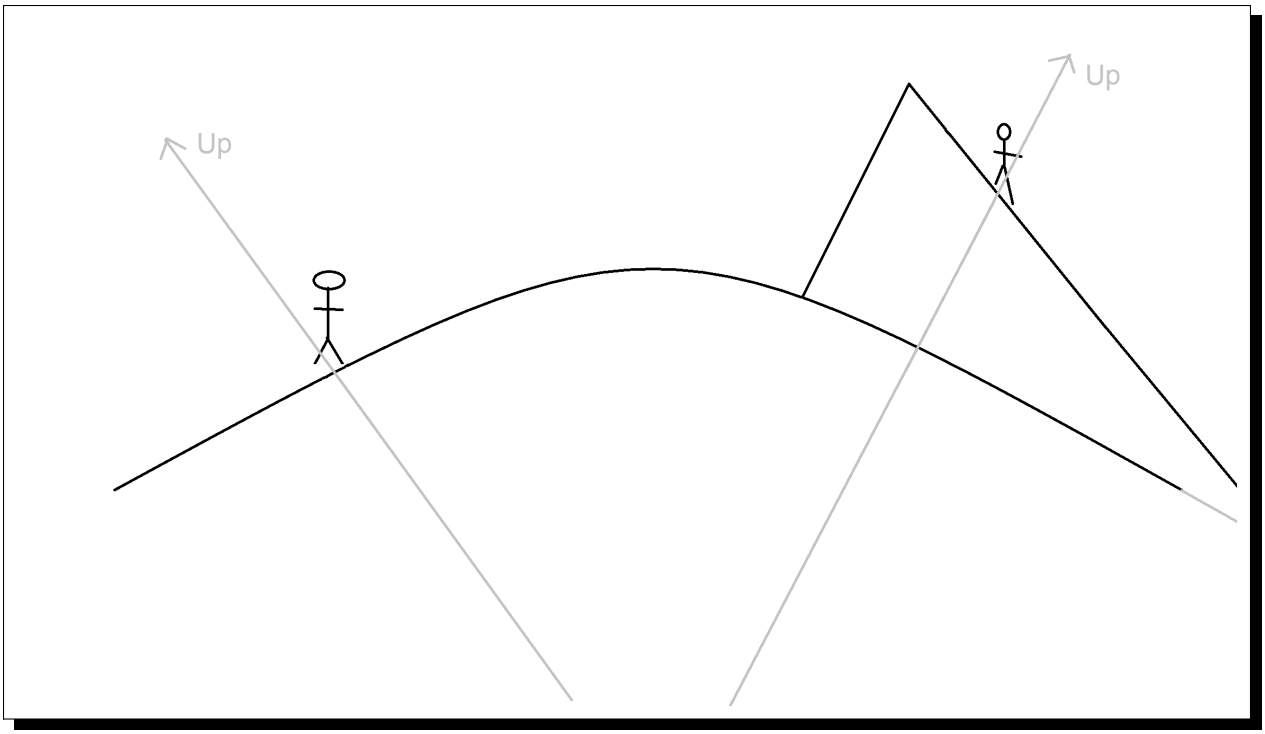


Intuitively we think of the ground as a flat surface, and height is simply the direction perpendicular to the ground. This works perfectly well for everyday usage such as a pirate burying treasure "6 feet below the ground".

However, if we introduce the concept of a hill to that mental model it starts to become ambiguous. If one person is standing at the bottom of a hill, and another person is standing on it…are they at the same height (actual ground level) or is one of them higher than the other?

Additionally, as any pirate who has every tried to look over the horizon from the crow's nest has figured out, the Earth is not, in fact, flat. It's possible to have a mountain ("higher") located "below" the horizon.

Up is the opposite of down



The actual, scientific answer to that conundrum is that "down" is the direction of gravity (i.e. towards the centre of the Earth), and "up" is the same axis just going the other way. That is, every point on the Earth measures "height" in a slightly different direction from every other point. That's not as bad as it initially sounds for a surveyor though because they can use a spirit level to determine what direction that is. It's fiddly and requires a lot of care but is doable, and a spirit level is part of every surveyors toolkit.

The results of those measurements reveal that the Earth's gravity does not actually point at the centre of the Earth. At first glance that seems it must be wrong, but if you think back to how the Earth isn't actually a perfect ellipsoid, and nor is the landmass on it equally distributed it starts to makes sense. The line of 0m height that is produced by keeping the spirit level level, is therefore not ellipsoidal but it also does not follow the contours of the Earth's physical surface. It is it's own unique imaginary shape (yes, another one) and is called the *local geoid*.

Note: Confusingly, "geoid height" refers to the distance between the *geoid* and the *ellipsoid*. The distance between the geoid and what you're measuring is called *orthometric height*.

Note: For most of a landmass, this does mean that just as an "ellipsoid height" is not related to anything the eye can see, neither are geoid based heights other than at that single primary marker point.

Although countries worldwide have tended to settle on using bodies of water to set their 0 height points, this is an arbitrary choice. It makes most of the country have positive height numbers which has practical benefits, but scientifically they could have chosen literally any point in the country to be 0 and done their spirit levelling from there instead. There are an infinite number of potential 0 heights that could have been picked with their corresponding geoids (before choosing sea level at Newlyn, UK mainland heights were actually measured from a church in Liverpool).

In the last few decades it has become possible to measure gravity from space. Not needing a stable surface and spirit level means that measuring a geoid does not need to stop at the coast anymore, but can continue over oceans too. That means that it is now possible for heights to actually be comparable and interoperable between different landmasses. This *global geoid* is defined as the geoid that most closely aligns with global mean sea level.

Note: This means the global geoid doesn't go through a single prone-to-destruction marker point and no country gets bragging rights to having the definition be based on their land, but it does involve measuring the entire ocean instead which obviously presents some practical difficulties.

Most national mapping therefore continue to use a local geoid, because it allows them to restrict the necessary survey work to within their own territory.

In summary, coordinates can measure heights in any of the following ways:

- a by-product of a 3-axis based geocentric coordinate system
- the distance from the imaginary ellipsoid, in the direction away from the centre of the ellipsoid
- the distance from an imaginary local geoid referenced to local mean sea level, in the opposite direction to gravity
- the distance from an imaginary global geoid referenced to global mean sea level, in the opposite direction to gravity

with absolutely none of them being referenced to actual physical ground characteristics at all.

Caution: This means if you're just trying to locate points on the Earth surface, it is probably better to use coordinates *without a height* rather than specify a zero height as that almost certainly doesn't mean what you intend it to.

And if you are trying to reference a height compared to local surface level ("the treasure is 6 feet below ground", "that building is 100 metres tall") specify that information separately to the coordinates.

Epochs

The Earth is not a static environment. Melting glaciers cause sea levels to change. Earthquakes cause land to suddenly shift in sudden (and often catastrophic) ways. And continental drift causes continents to slowly, but continuously change position. It is therefore important for high accuracy to record *when* the measurements were made. This date portion of a coordinate is called an *epoch*.

True Story

An operator of 2 oil platforms located near each other wanted to install a bridge between them. The first platform was installed in the 1990s, the second was installed in the 2010s. Both platforms had accurate locations recorded at time of installation, and so the corresponding distance and angle between them were calculated and a bridge was pre-fabricated on-shore and brought to sea.

It didn't fit. The calculated gap between them was wrong because the coordinates of the two platforms were taken 20 years apart. This mistake cost **millions** to fix.

Tip: Geodesy tends to use decimal years for epochs, e.g. 2000.40, or 2021.00. For ease of use PHPCoord deviates from this and accepts dates in standard PHP `DateTime`/`DateTimeImmutable` format instead.

If, like most people you don't have dates for your coordinates, you can also use `null` or leave blank entirely. Doing this means that PHPCoord will infer the current date when converting coordinates between systems.

1.2.2 EPSG codes

EPSG

The oil and gas industry relies very heavily upon precision surveying - accurate information as to location is of critical importance to them, not just on a day-to-day "is this drill positioned where we think it is?" basis but also for legal and regulatory purposes such as obtaining the necessary licenses. Given that almost every country in the world has its own coordinate system(s) and also that oil and gas fields do not stop at national boundaries, the ability to convert between them is a frequent necessity.

For that reason, one of their trade associations, the International Association of Oil & Gas Producers (IOGP) maintains a database of coordinate system definitions and how to transform between them for use by their members known as the EPSG Geodetic Parameter Dataset. They also generously make it available at no charge to non-members.

This dataset (maintained since 1985, public since 1993) is so useful that it has become a de-facto standard, and it is incorporated into many, many GIS applications. The usage of "EPSG codes" to reference specific coordinate systems has actually become so standardised that IOGP accepts submissions for new ones that have absolutely no relevance to their own members.

Example EPSG codes you may have seen include:

- EPSG:4326 for WGS84 (GPS)
- EPSG:4269 for NAD83 (North America)
- EPSG:4258 for ETRS89 (Europe)

PHPCoord also makes use of the EPSG dataset although for the most part tries to make it an implementation detail rather than something that users should be aware of. It is possible to use EPSG codes directly if you know them (e.g. taking in data from an external system), but it's not necessary to know the relevant code to use the software.

1.3 Creating points

In PHPCoord, the core domain object is a `Point`. A `Point` is constructed from set of coordinates (for example latitude and longitude), and a *Coordinate Reference System (CRS)* which encodes all of the parameters that make a particular system different from any other system. PHPCoord contains built-in knowledge of 6982 different CRSs, so in almost all cases you only need to know the CRS name rather than the individual defining parameters. A full list of built-in CRSs is *available here*.

Ideally (but optionally), a `Point` also has a *coordinate epoch* aka the date the coordinates are intended to represent. This is important for high-accuracy applications as *explained here*.

Each CRS contains within its definition the units of measurement to be used - for example the British National Grid uses metres, but the Arkansas State Plane Coordinate System uses US Survey Feet. To avoid any confusion about representation, all numbers in PHPCoord are strongly typed as value objects with conversions automatically performed between them as needed. All outputs are in the defined units of the relevant CRS, even if the inputs were given in different units. You may of course convert these units into other units if desired, but using units that are different from those defined in the CRS itself may lead to confusion later on.

1.3.1 Geographic points

A geographic point is one that has a *latitude* and a *longitude*. It may also include a height, but only if the height is an *ellipsoid height*. If you have a *local*, *geoid* or *orthometric* height, then you will need a both a `GeographicPoint` and a `VerticalPoint` and then to tie them together with a `CompoundPoint`.

A `GeographicPoint` can be constructed by calling `GeographicPoint::create`, which has the following signature:

```
public static function create(
    Geographic $crs,
    Angle $latitude,
    Angle $longitude,
    ?Length $height = null,
    ?DateTimeInterface $epoch = null
): GeographicPoint
```

For `$crs` use a `Geographic3D` CRS if you are supplying height, or a `Geographic2D` CRS if you are not.

Examples:

```
<?php
use PHPCoord\CoordinateReferenceSystem\Geographic2D;
use PHPCoord\Point\GeographicPoint;
use PHPCoord\UnitOfMeasure\Angle\Degree;

// the Statue of Liberty in WGS84 (unknown date), traditional arguments, decimal degrees
$crs = Geographic2D::fromSRID(Geographic2D::EPSG_WGS_84);
$point = GeographicPoint::create(
    $crs,
    new Degree(40.689167),
    new Degree(-74.044444),
    null
);

// the Statue of Liberty in WGS84 (2020-02-01), traditional arguments, string␣
↪representation of degrees
$crs = Geographic2D::fromSRID(Geographic2D::EPSG_WGS_84);
$point = GeographicPoint::create(
    $crs,
    Degree::fromDegreeMinuteSecondHemisphere('40° 41 21 N'),
    Degree::fromDegreeMinuteSecondHemisphere('74° 2 40 W'),
    null,
    new DateTime('2020-02-01')
);

// the Statue of Liberty in WGS84 (unknown date), named arguments, decimal degrees
$crs = Geographic2D::fromSRID(Geographic2D::EPSG_WGS_84);
```

(continues on next page)

(continued from previous page)

```php
$point = GeographicPoint::create(
    latitude: new Degree(40.689167),
    longitude: new Degree(-74.044444),
    crs: $crs
);

// the Statue of Liberty in WGS84 (2020-02-01), named arguments, string representation
↪of degrees
$crs = Geographic2D::fromSRID(Geographic2D::EPSG_WGS_84);
$point = GeographicPoint::create(
    latitude: Degree::fromDegreeMinuteSecondHemisphere('40° 41 21 N'),
    longitude: Degree::fromDegreeMinuteSecondHemisphere('74° 2 40 W'),
    epoch: new DateTime('2020-02-01'),
    crs: $crs
);

$latitude = $point->getLatitude(); // Angle
$longitude = $point->getLongitude(); // Angle
$height = $point->getHeight(); // Length|null
$epoch = $point->getCoordinateEpoch(); // DateTimeImmutable|null
$crs = $point->getCRS(); // Geographic2D|Geographic3D
$asString = (string) $point; // '(40.689167, -74.044444)'
```

1.3.2 Projected points

A projected point is one that has an *east-west* distance and a *north-south* distance. These are most often called *eastings* and *northings*, but sometimes *westings* and/or *southings* are used instead. Some coordinate systems eschew directional naming and use just *x* and *y* instead, the meaning of which varies. PHPCoord's input always uses the directional naming system.

If you have coordinates `(x,y,h)`, then you *may* need a 3D projected point, but you *probably* need a 2D `ProjectedPoint` plus a `VerticalPoint`, and then to tie them together with a `CompoundPoint`. Only if `h` represents ellipsoidal height should `h` be used as a third dimension when constructing a `ProjectedPoint`.

Note: Within the built-in PHPCoord systems, only `Projected::EPSG_LUREF_LUXEMBOURG_TM_3D` is a 3D system, all others are 2D.

Caution: Do not confuse `(x,y,h)` with `(x,y,z)`. `(x,y,z)` is used by Geocentric coordinate systems.

A `ProjectedPoint` can be constructed by calling one of the `ProjectedPoint::create*` methods, which have the following signatures:

```php
public static function createFromEastingNorthing(
    Projected $crs,
    Length $easting,
    Length $northing,
    ?DateTimeInterface $epoch = null,
    ?Length $height = null
```

(continues on next page)

(continued from previous page)

```
): ProjectedPoint

public static function createFromWestingNorthing(
    Projected $crs,
    Length $westing,
    Length $northing,
    ?DateTimeInterface $epoch = null,
    ?Length $height = null
): ProjectedPoint

public static function createFromWestingSouthing(
    Projected $crs,
    Length $westing,
    Length $southing,
    ?DateTimeInterface $epoch = null,
    ?Length $height = null
): ProjectedPoint
```

Examples:

```
<?php
use PHPCoord\CoordinateReferenceSystem\Projected;
use PHPCoord\Point\ProjectedPoint;
use PHPCoord\UnitOfMeasure\Length\Metre;

// Nelson's Column in British National Grid (unknown date), traditional arguments
$crs = Projected::fromSRID(Projected::EPSG_OSGB36_BRITISH_NATIONAL_GRID);
$point = ProjectedPoint::createFromEastingNorthing(
    $crs,
    new Metre(530017),
    new Metre(180419)
);

// Nelson's Column in British National Grid (2020-02-01), traditional arguments
$crs = Projected::fromSRID(Projected::EPSG_OSGB36_BRITISH_NATIONAL_GRID);
$point = ProjectedPoint::createFromEastingNorthing(
    $crs,
    new Metre(530017),
    new Metre(180419),
    new DateTime('2020-02-01')
);

// Nelson's Column in British National Grid (unknown date), named arguments

    easting: new Metre(530017),
    northing: new Metre(180419),
    crs: $crs
);

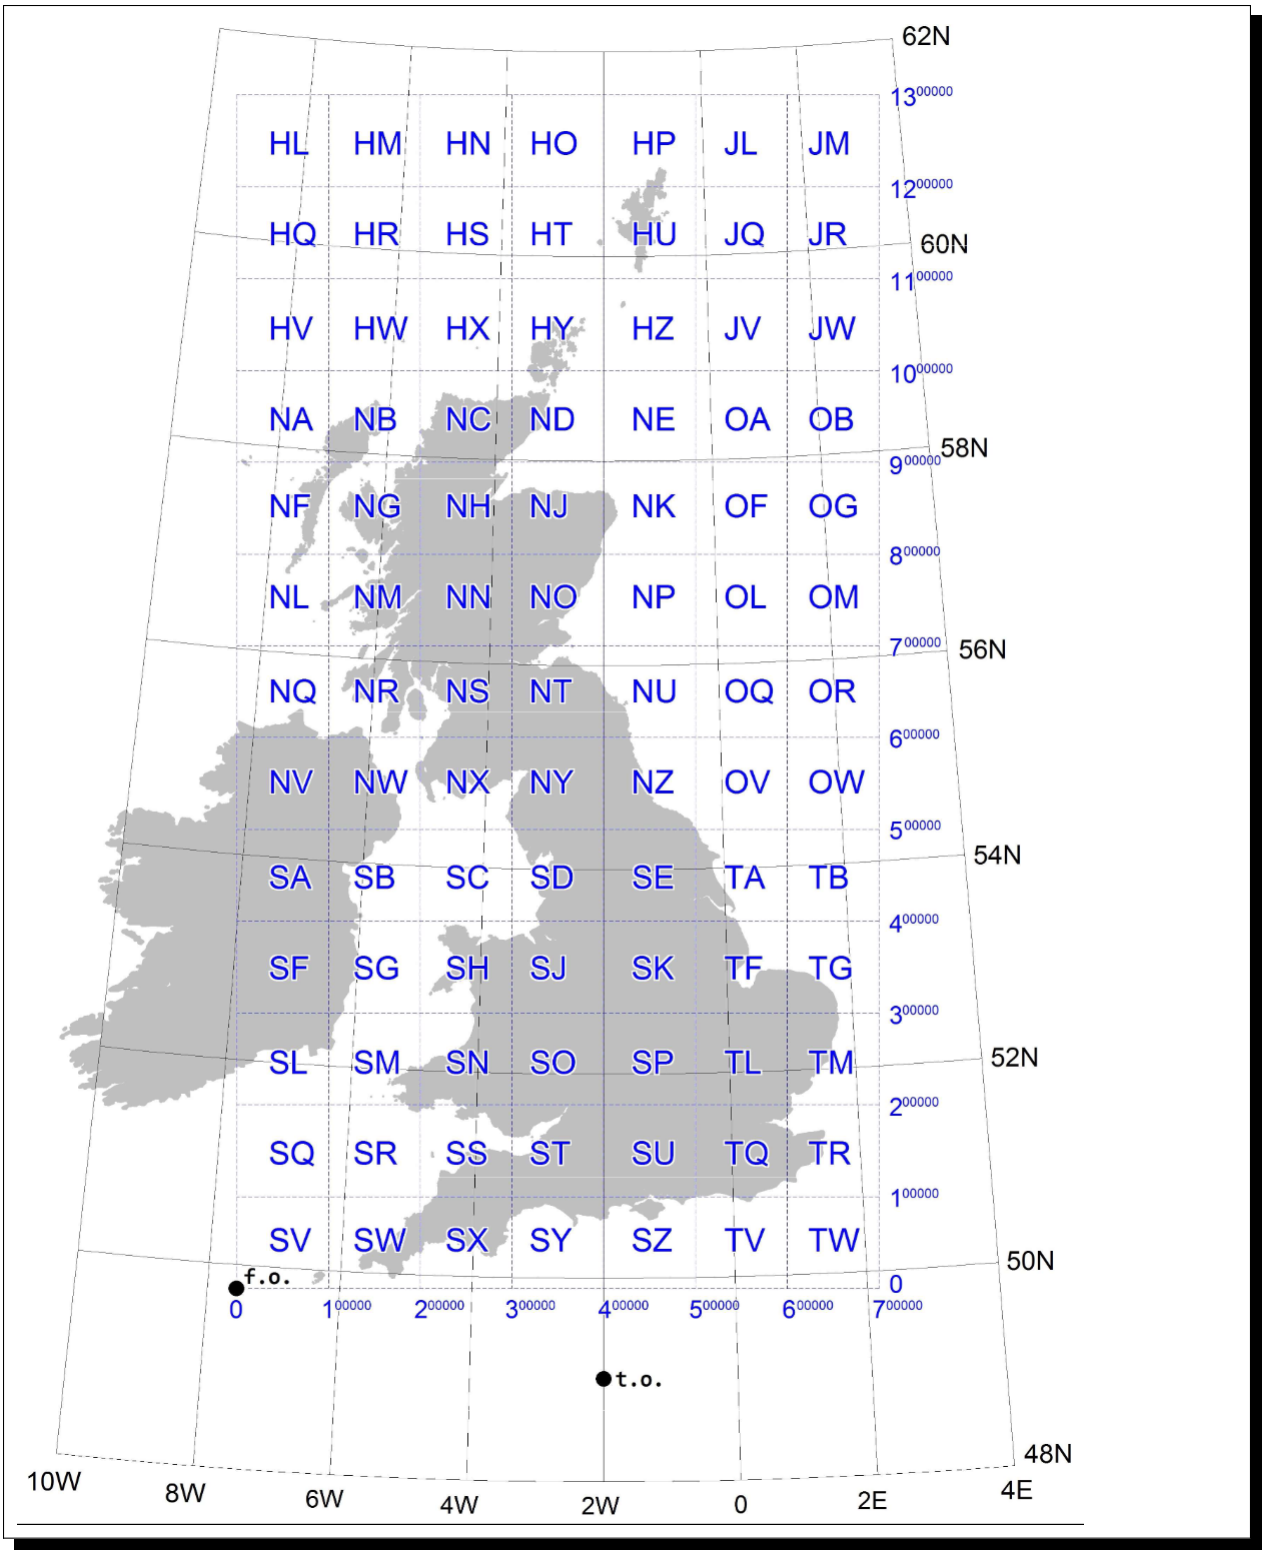
British National Grid

GB grid references



(also known as Ordnance Survey National Grid)

In Great Britain, the convention is not to use as-is the easting and northing coordinates produced by the projection. The country is divided into sub-grids of 100km×100km which are given 2 letter codes, and then coordinates are given referenced to their position within the subgrid rather than the national origin. Thus, Nelson's Column `(530017, 180419)`

would usually be referred to as `TQ 30017 80419`. Exchanging numbers for letters in this way sounds complex, but having the grid letters aids greatly in finding the right map sheet when working with paper maps.

Using the letters also clearly distinguishes between "pure" eastings/northings and the grid system. This has the benefit that it becomes permissible to truncate coordinates when full metre-level precision is not required, e.g. when trying to locate a building. For example, if just trying to locate Trafalger Square as a whole rather than specifically Nelson's statue, a coordinate like `TQ 300 804` could be given which is accurate to ~100m. This would not be possible to give purely numerically, as it could be confused with an actual full coordinate for a different point.

A `BritishNationalGridPoint` is automatically created from `ProjectedPoint::createFromEastingNorthing()` if the relevant CRS is supplied - the examples above all actually create a `BritishNationalGridPoint` rather than a standard `ProjectedPoint`. Alternatively, you can construct one directly.

```
// from full eastings and northings
public function __construct(
    Length $easting,
    Length $northing,
    ?DateTimeInterface $epoch = null
): BritishNationalGridPoint

// from a grid reference
public static function fromGridReference(
    string $reference,
    ?DateTimeInterface $epoch = null
): BritishNationalGridPoint
```

Examples:

```
<?php
use PHPCoord\CoordinateReferenceSystem\Projected;
use PHPCoord\Point\BritishNationalGridPoint;
use PHPCoord\Point\ProjectedPoint;
use PHPCoord\UnitOfMeasure\Length\Metre;

// Nelson's Column
$crs = Projected::fromSRID(Projected::EPSG_OSGB36_BRITISH_NATIONAL_GRID);
$point = ProjectedPoint::createFromEastingNorthing(
    $crs,
    new Metre(530017),
    new Metre(180419)
);

// also Nelson's Column
$point = new BritishNationalGridPoint(new Metre(530017), new Metre(180419)); // CRS is␣
↪implied

// also Nelson's Column
$point = BritishNationalGridPoint::fromGridReference('TQ 30017 80419'); // CRS is implied

$isBritishGrid = $point instanceof BritishNationalGridPoint; //true
$asString = (string) $point; // '(530017, 180419)'
$asString = $point->asGridReference(10); // 'TQ3001780419'
$asString = $point->asGridReference(6); // 'TQ300804'
$asString = $point->asGridReferenceWithSpaces(10); // 'TQ 30017 80419'
$asString = $point->asGridReferenceWithSpaces(6); // 'TQ 300 804'
```

Irish Grid

Ireland adopted a similar system to Britain that also uses grid letters. Each 100km×100km grid square in Ireland is identified by a single letter rather than by two, in other respects the system is near identical.

A `IrishGridPoint` is automatically created from `ProjectedPoint::createFromEastingNorthing()` if the relevant CRS is supplied. Alternatively, you can construct one directly.

```
// from full eastings and northings
public function __construct(
    Length $easting,
    Length $northing,
    ?DateTimeInterface $epoch = null
): IrishGridPoint

// from  a grid reference
public static function fromGridReference(
    string $reference,
    ?DateTimeInterface $epoch = null
): IrishGridPoint
```

Examples:

```
<?php
use PHPCoord\CoordinateReferenceSystem\Projected;
use PHPCoord\Point\IrishGridPoint;
use PHPCoord\Point\ProjectedPoint;
use PHPCoord\UnitOfMeasure\Length\Metre;

// Spire of Dublin
$crs = Projected::fromSRID(Projected::EPSG_TM75_IRISH_GRID);
$point = ProjectedPoint::createFromEastingNorthing(
    $crs,
    new Metre(315904),
    new Metre(234671)
);

// also Spire of Dublin
$point = new IrishGridPoint(new Metre(315904), new Metre(234671)); // CRS is implied

// also Spire of Dublin
$point = IrishGridPoint::fromGridReference('O1590434671'); // CRS is implied

$isIrishGrid = $point instanceof IrishGridPoint; //true
$asString = (string) $point; // '(315904, 234671)'
$asString = $point->asGridReference(10); // 'O1590434671'
$asString = $point->asGridReference(6); // 'O159346'
$asString = $point->asGridReferenceWithSpaces(10); // 'O 15904 34671'
$asString = $point->asGridReferenceWithSpaces(6); // 'O 159 346'
```

Irish Transverse Mercator

In 2001, Ireland introduced a replacement system for the Irish Grid system known as Irish Transverse Mercator (ITM). In ITM eastings and northings are always given in full. ITM does not use grid letters.

Nonetheless, PHPCoord comes with a dedicated `IrishTransverseMercatorPoint` class. This class exists only to try and mitigate any confusion in advance between the two systems - a developer who was not aware of the older system, might accidentally try to use a `IrishGridPoint` thinking it was the right thing to do when they actually have coordinates in the ITM system. The class has no additional functionality over a standard `ProjectedPoint`.

```
// from full eastings and northings
public function __construct(
    Length $easting,
    Length $northing,
    ?DateTimeInterface $epoch = null
): IrishTransverseMercatorPoint
```

Examples:

```
<?php
use PHPCoord\CoordinateReferenceSystem\Projected;
use PHPCoord\Point\IrishTransverseMercatorPoint;
use PHPCoord\Point\ProjectedPoint;
use PHPCoord\UnitOfMeasure\Length\Metre;

// Spire of Dublin
$crs = Projected::fromSRID(Projected::EPSG_IRENET95_IRISH_TRANSVERSE_MERCATOR);
$point = ProjectedPoint::createFromEastingNorthing(
    $crs,
    new Metre(715830),
    new Metre(734697),
);

// also Spire of Dublin
$point = new IrishTransverseMercatorPoint(new Metre(715830), new Metre(734697)); // CRS␣
↪is implied

$isITM = $point instanceof IrishTransverseMercatorPoint; //true
$asString = (string) $point; // '(715830, 734697)'
```

Universal Transverse Mercator (UTM)

Although one of the most widely used applications of the Transverse Mercator projection, UTM is not actually a map projection. It's a *system* of map projections, and this distinction means that it does not fit neatly into the standard data model. Mathematically each UTM zone/hemisphere combination is its own unique projection and therefore to work with the data you also need to know which zone/hemisphere the coordinates are referenced to. Adding a further layer of complication is that although UTM is most commonly used alongside WGS84, it can be used with any Geographic CRS so that information needs to be known as well.

PHPCoord has 3 ways to handle this issue.

Treat each zone/hemisphere as a fully independent projection

Pros: no confusion about what the coordinates represent
Cons: when converting to UTM, you need to know in advance which zone/hemisphere the points reside in

For many `Geographic2D` CRSs, there are corresponding dedicated `Projected` CRS for each individual UTM zone and hemisphere. In total there are over 1000 individual such CRSs defined.

Examples:

```php
<?php
use PHPCoord\CoordinateReferenceSystem\Projected;
use PHPCoord\Point\ProjectedPoint;
use PHPCoord\UnitOfMeasure\Length\Metre;

// Piazza San Marco, Venice
$crs = Projected::fromSRID(Projected::EPSG_WGS_84_UTM_ZONE_33N);
$point = ProjectedPoint::createFromEastingNorthing(
    $crs,
    new Metre(291789),
    new Metre(5034599),
);

// Piazza San Marco, Venice
$crs = Projected::fromSRID(Projected::EPSG_ETRS89_UTM_ZONE_33N);
$point = ProjectedPoint::createFromEastingNorthing(
    $crs,
    new Metre(291789),
    new Metre(5034599),
);
```

Prefix easting with the zone

Pros: you only have to know the hemisphere when converting to UTM (i.e. is latitude $\pm$ 0)
Cons: coordinates are not distances, WGS84 only

Because the previously described system has some practical difficulties in use when working with points that are not all from within a single zone, this alternate mechanism is sometimes used. It works by (ab)using the easting coordinate to store the zone number alongside the actual coordinate resulting from the projection.

> **Warning:** Normally the coordinates of a map projection represent real distances on the ground. For UTM, these would be distance in metres from the origin. However when zone numbers are incorporated into the easting in this way, then that is no longer true - an easting of 32500000 and an easting of 33500000 are **not** 1000000m apart.
>
> The prefix-based mechanism is made available in PHPCoord for interoperability with other systems, but is discouraged for use.

Example:

```php
<?php
use PHPCoord\CoordinateReferenceSystem\Projected;
use PHPCoord\Point\ProjectedPoint;
use PHPCoord\UnitOfMeasure\Length\Metre;

// Piazza San Marco, Venice
$crs = Projected::fromSRID(Projected::EPSG_WGS_84_UTM_GRID_SYSTEM_NORTHERN_HEMISPHERE);
$point = ProjectedPoint::createFromEastingNorthing(
    $crs,
    new Metre(33291789), // UTM is defined as metres, but this coordinate is actually␣
↪not...
    new Metre(5034599)
);
```

Treat UTM as special

Pros: no pre-calculation needed to determine hemisphere or zone number when converting
Cons: potentially less interoperability with other systems (does not fit into the EPSG data model)

PHPCoord also offers a way to work with UTM where the zone number and hemisphere are treated as first-class aspects of the data model rather than shoehorned into one of the coordinates or needing to be extrapolated from the name of the CRS. This is done via `UTMPoint` which is a specialised extension of `ProjectedPoint`.

```php
public function __construct(
    Geographic $crs,
    Length $easting,
    Length $northing,
    int $zone,
    string $hemisphere, //one of UTMPoint::HEMISPHERE_NORTH or UTMPoint::HEMISPHERE_SOUTH
    ?DateTimeInterface $epoch = null
): UTMPoint
```

Example:

```php
<?php
use PHPCoord\CoordinateReferenceSystem\Geographic;
use PHPCoord\Point\UTMPoint;
use PHPCoord\UnitOfMeasure\Length\Metre;

// Piazza San Marco, Venice
$crs = Geographic2D::fromSRID(Geographic2D::EPSG_WGS_84);
$point = new UTMPoint(
    $crs,
    new Metre(291789),
    new Metre(5034599),
    33,
    UTMPoint::HEMISPHERE_NORTH,
);

$easting = $point->getEasting(); // Metre
```

(continues on next page)

(continued from previous page)

```
$northing = $point->getNorthing(); // Metre
$zone = $point->getZone(); // int
$hemisphere = $point->getHemisphere(); // UTMPoint::HEMISPHERE_
↪NORTH|UTMPoint::HEMISPHERE_SOUTH
$epoch = $point->getCoordinateEpoch(); // DateTimeImmutable|null
$baseCRS = $point->getBaseCRS(); // Geographic
$crs = $point->getCRS(); // Projected (synthesised at runtime, not one from the built-in␣
↪EPSG set)
$asString = (string) $point; // '33N 291789 5034599'
```

1.3.3 Geocentric points

A geocentric point is one that measures distances from the centre of the Earth. These are usually in `(x,y,z)` format.

A `GeocentricPoint` can be constructed by calling `GeocentricPoint::create` which has the following signature:

```
public static function create(
    Geocentric $crs,
    Length $x,
    Length $y,
    Length $z,
    ?DateTimeInterface $epoch = null
): GeocentricPoint
```

Examples:

```
<?php
use PHPCoord\CoordinateReferenceSystem\Geocentric;
use PHPCoord\Point\GeocentricPoint;
use PHPCoord\UnitOfMeasure\Length\Metre;

// Ascension Island GPS tracking station in ITRF2008 (unknown date), traditional␣
↪arguments
$crs = Geocentric::fromSRID(Geocentric::EPSG_ITRF2008);
$point = GeocentricPoint::create(
    $crs,
    new Metre(6121152),
    new Metre(-1563979),
    new Metre(-872615)
);

// Ascension Island GPS tracking station in ITRF2008 (2020-02-01), traditional arguments
$crs = Geocentric::fromSRID(Geocentric::EPSG_ITRF2008);
$point = GeocentricPoint::create(
    $crs,
    new Metre(6121152),
    new Metre(-1563979),
    new Metre(-872615),
    new DateTime('2020-02-01')
);

// Ascension Island GPS tracking station in ITRF2008 (unknown date), named arguments
```

(continues on next page)

(continued from previous page)

```php
$crs = Geocentric::fromSRID(Geocentric::EPSG_ITRF2008);
$point = GeocentricPoint::create(
    x: new Metre(6121152),
    y: new Metre(-1563979),
    z: new Metre(-872615),
    crs: $crs
);

// Ascension Island GPS tracking station in ITRF2008 (2020-02-01), named arguments
$crs = Geocentric::fromSRID(Geocentric::EPSG_ITRF2008);
$point = GeocentricPoint::create(
    x: new Metre(6121152),
    y: new Metre(-1563979),
    z: new Metre(-872615),
    epoch: new DateTime('2020-02-01'),
    crs: $crs
);

$x = $point->getX(); // Length
$y = $point->getY(); // Length
$z = $point->getZ(); // Length
$epoch = $point->getCoordinateEpoch(); // DateTimeImmutable|null
$crs = $point->getCRS(); // Geocentric
$asString = (string) $point; // '(6121152, -1563979, -872615)'
```

1.3.4 Vertical points

A vertical point is one that has a *height* (or *depth* as negative) component only. Since this is of limited practical use, they are usually paired with 2D `GeographicPoint` or a `ProjectedPoint` as part of a `CompoundPoint`.

A `VerticalPoint` can be constructed by calling `VerticalPoint::create`, which has the following signature:

```php
public static function create(
    Vertical $crs,
    Length $height,
    ?DateTimeInterface $epoch = null
): VerticalPoint
```

Examples:

```php
<?php
use PHPCoord\CoordinateReferenceSystem\Vertical;
use PHPCoord\Point\VerticalPoint;
use PHPCoord\UnitOfMeasure\Length\Metre;

// an arbitrary height in New Zealand Vertical Datum (unknown date), traditional␣
↪arguments
$crs = Vertical::fromSRID(Vertical::EPSG_NZVD2016_HEIGHT);
$point = VerticalPoint::create(
    $crs,
    new Metre(12.34),
);
```

(continues on next page)

(continued from previous page)

```php
// an arbitrary height in New Zealand Vertical Datum (2020-02-01), traditional arguments
$crs = Vertical::fromSRID(Vertical::EPSG_NZVD2016_HEIGHT);
$point = VerticalPoint::create(
    $crs,
    new Metre(12.34),
    new DateTime('2020-02-01')
);

// an arbitrary height in New Zealand Vertical Datum (unknown date), named arguments
$crs = Vertical::fromSRID(Vertical::EPSG_NZVD2016_HEIGHT);
$point = VerticalPoint::create(
    height: new Metre(12.34),
    crs: $crs
);

// an arbitrary height in New Zealand Vertical Datum (2020-02-01), named arguments
$crs = Vertical::fromSRID(Vertical::EPSG_NZVD2016_HEIGHT);
$point = VerticalPoint::create(
    height: new Metre(12.34),
    epoch: new DateTime('2020-02-01'),
    crs: $crs
);

$height = $point->getHeight(); // Length
$epoch = $point->getCoordinateEpoch(); // DateTimeImmutable|null
$crs = $point->getCRS(); // Vertical
$asString = (string) $point; // '(12.34)'
```

1.3.5 Compound points

A compound point ties together horizontal coordinates (2D) and a vertical coordinate (1D) to fully locate a point in 3D.

A `CompoundPoint` can be constructed by calling `CompoundPoint::create`, which has the following signature:

```php
public static function create(
    Compound $crs,
    GeographicPoint|ProjectedPoint $horizontalPoint,
    VerticalPoint $verticalPoint,
    ?DateTimeInterface $epoch = null
): CompoundPoint
```

Example:

```php
<?php
use PHPCoord\CoordinateReferenceSystem\Projected;
use PHPCoord\CoordinateReferenceSystem\Vertical;
use PHPCoord\Point\CompoundPoint;
use PHPCoord\Point\ProjectedPoint;
use PHPCoord\Point\VerticalPoint;
use PHPCoord\UnitOfMeasure\Length\Metre;
```

(continues on next page)

(continued from previous page)

```php
// Horizontal location of Ben Nevis peak using British National Grid
$horizontalCRS = Projected::fromSRID(Projected::EPSG_OSGB36_BRITISH_NATIONAL_GRID);
$horizontalPoint = ProjectedPoint::createFromEastingNorthing(
    $horizontalCRS,
    new Metre(216692),
    new Metre(771274)
);

// Height above Newlyn Sea Level of Ben Nevis peak
$verticalCRS = Vertical::fromSRID(Vertical::EPSG_ODN_HEIGHT);
$verticalPoint = VerticalPoint::create(
    $verticalCRS,
    new Metre(1345)
);

// Full coordinate of Ben Nevis Peak
$compoundCRS = Compound::fromSRID(Compound::EPSG_OSGB36_BRITISH_NATIONAL_GRID_PLUS_ODN_
↪HEIGHT);
$point = CompoundPoint::create(
    $compoundCRS,
    $horizontalPoint,
    $verticalPoint
);

$horizontal = $point->getHorizontalPoint(); // GeographicPoint|ProjectedPoint
$vertical = $point->getVerticalPoint(); // VerticalPoint
$epoch = $point->getCoordinateEpoch(); // DateTimeImmutable|null
$crs = $point->getCRS(); // Compound
$asString = (string) $point; // '((216692, 771274), (1345))'
```

1.4 Coordinate conversions

PHPCoord can convert coordinates representing a point from one *Coordinate Reference System (CRS)* to another one. In this simplest case this might just be converting units (e.g. feet to metres or vice versa), but in most cases involves running one or more complex algorithms on the numbers.

Most such algorithms are not standalone, but require parameters to work - for instance many require an origin point to be specified and these points differ across mapping systems even when they utilise the same algorithm. Knowing both the algorithm(s) to be used and the parameters used to tune them is essential to perform high-accuracy conversions.

PHPCoord offers two models of operation for coordinate conversion:

- The hard way in which you can directly utilise one of the many implemented algorithms along with the parameters of your choice to keep full control over the conversion
- The easy way in which PHPCoord consults the built-in EPSG dataset for the relevant algorithm(s) to use and best parameters to use for your chosen conversion and executes them behind the scenes on your behalf.

1.4.1 The easy way

When working with the built-in *Coordinate Reference Systems*, PHPCoord can usually convert the coordinates in any given `Point` to be in a different system by calling the `convert()` method.

```
$newPoint = $point->convert(
    CoordinateReferenceSystem $to,
    bool $ignoreBoundaryRestrictions = false
); // returns a new Point
```

Examples:

```
<?php
use PHPCoord\CoordinateReferenceSystem\Geographic2D;
use PHPCoord\CoordinateReferenceSystem\Projected;
use PHPCoord\Point\GeographicPoint;
use PHPCoord\UnitOfMeasure\Angle\Degree;

// Converting from NAD83 to Florida State Plane
$from = GeographicPoint::create(
    Geographic2D::fromSRID(Geographic2D::EPSG_NAD83),
    new Degree(28.46),
    new Degree(-80.53),
    null
);
$toCRS = Projected::fromSRID(Projected::EPSG_NAD83_FLORIDA_EAST);
$to = $from->convert($toCRS); // $to instanceof ProjectedPoint
```

```
<?php
use PHPCoord\CoordinateReferenceSystem\Geographic2D;
use PHPCoord\CoordinateReferenceSystem\Projected;
use PHPCoord\Point\ProjectedPoint;
use PHPCoord\UnitOfMeasure\Length\Metre;

// Converting from Florida State Plane to NAD83
$from = ProjectedPoint::createFromEastingNorthing(
    Projected::fromSRID(Projected::EPSG_NAD83_FLORIDA_EAST)
    new Metre(246029.85),
    new Metre(457274.616)
);
$toCRS = Geographic2D::fromSRID(Geographic2D::EPSG_NAD83);
$to = $from->convert($toCRS); // $to instanceof GeographicPoint
```

Ignoring the second optional parameter for now, calling `convert()` will consult the built-in dataset and if a conversion is found, then PHPCoord will automatically invoke the relevant conversion method with the appropriate parameters (see the "hard" section), returning a new `Point` object with the adjusted coordinates.

Although PHPCoord has knowledge of thousands of different conversions, this does not cover many scenarios. For example there is no published direct conversion between a British National Grid reference and a WGS84 UTM Grid reference. In these scenarios PHPCoord can "chain" conversions it does know about to achieve the desired result, for example it would automatically calculate British National Grid -> OSGB36 -> WGS84 -> UTM. This ability to chain means conversion between almost any two CRSs is possible as long as they have a common link.

```php
$from = ProjectedPoint::createFromEastingNorthing(
    Projected::fromSRID(Projected::EPSG_OSGB36_BRITISH_NATIONAL_GRID),
    new Metre(577275),
    new Metre(69741)
);
$toCRS = Projected::fromSRID(Projected::EPSG_WGS_84_UTM_ZONE_31N);
$to = $from->convert($toCRS);
```

Note: Calculating every single possible permutation of chain between two CRSs is very computationally expensive and so for practicality PHPCoord limits the chain depth to 7 (i.e. the source CRS, 5 intermediate CRSs and the target CRS). If you know a transformation should be possible, but PHPCoord cannot find it you may wish to try an explicit 2-stage conversion (e.g. source to WGS84, WGS84 to target).

Boundaries

Every CRS has a defined area ("extent") over which it operates. Some are worldwide (e.g. WGS84), but most are regional (e.g. NAD83) or country-specific (e.g. GDA94). When converting points between different coordinate systems, it's important that these extents are respected, as any conversion formulas are only valid within the specified area of operation. For instance taking a point located in Tokyo and trying to obtain the New Zealand Map Grid coordinate for it is a nonsensical operation - theoretically you could find a chain of conversions (e.g. perhaps through WGS84) that would would produce *a* coordinate, but it would not be in the expected spot when plotting it onto an actual map.

PHPCoord will not normally allow such conversions to take place.

There are occasions however where the formal definitions of the CRS and real-life conflict - for example in Germany (which is partially in UTM zone 32 and partially in zone 33), coordinates are sometimes requested as zone 32-based even for points that are in zone 33. The administrative convenience is considered to outweigh the slight loss of accuracy of extending the zone.

If you are sure that you know what you're doing, you can set the optional parameter `$ignoreBoundaryRestrictions` to `true` to remove these boundary checks. Conversions between coordinate systems located in different regions (e.g. USA to UK, or Japan to NZ) will still be disallowed.

Note: For more on how PHPCoord implements boundaries/extents, *see below*.

Caution: The importance of boundary checking to ensure fidelity of results means that converting a standalone `VerticalPoint` cannot safely be done. `VerticalPoint` objects therefore do not have a `->convert` method.

In practice this should not affect you as a `VerticalPoint` will normally be used as part of a `CompoundPoint`.

Universal Transverse Mercator (UTM)

PHPCoord has 3 different ways of handling UTM references (*see here for details*).

For conversions that *do not* involve a `UTMPoint`, use the `->convert()` method as described above.

For conversions from a `GeographicPoint` to a `UTMPoint`, call the `->asUTMPoint()` method.

```
$from = GeographicPoint::create(
    Geographic2D::fromSRID(Geographic2D::EPSG_WGS_84),
    new Degree(43.642567),
    new Degree(-79.387139),
    null
);
$to = $from->asUTMPoint();
```

Note: You cannot directly convert to a `UTMPoint` from a different kind of `ProjectedPoint` or a `GeocentricPoint`, you must convert to the relevant `GeographicPoint` first. This is because the projection parameters are calculated dynamically at runtime and are not available to take part in chain creation.

For conversions from a `UTMPoint` back to the associated `GeographicPoint`, call the `->asGeographicPoint()` method.

```
$from = new UTMPoint(
    new Metre(630084),
    new Metre(4833439),
    17,
    UTMPoint::HEMISPHERE_NORTH,
    Geographic2D::fromSRID(Geographic2D::EPSG_WGS_84)
);
$to = $from->asGeographicPoint();
```

The `->convert()` method *is* present on `UTMPoint`s and can be used as normal to convert to any desired CRS (including the base CRS).

Accuracy

If the Earth were actually the shape of an ellipsoid, algorithms could be devised so that conversions between systems could be performed with no absolutely no loss of accuracy - systems would in effect be mathematically equivalent.

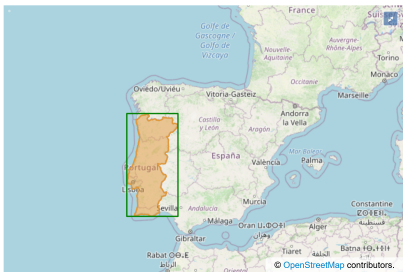
Unfortunately the Earth isn't an ellipsoid and coordinates are determined by individual humans operating on the Earth's actual, irregular surface using instruments subject to observation error. That means that conversions between CRSs are not just converting between mathematical ideals but often convert between *sets of observations*. When this happens it means that the conversions between the CRSs can only ever be an approximation (typically within a few metres) rather than exact.

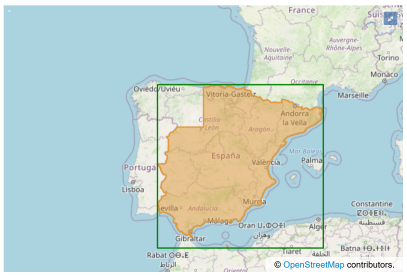
Extents

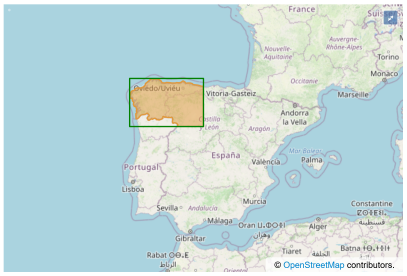
When dealing with CRSs that cover significant land area it is possible (and common) for mapping agencies to derive multiple different parameter sets for use to obtain better accuracy depending on location. For example when converting from ED50 to ETRS89 different parameters should be used for a point inside France than a point inside Denmark.

In order to be able to do conversions successfully, PHPCoord therefore needs to know not just the geographical extents of each coordinate system but also (where different), the geographical extents of each possible set of conversion parameters.

For a closer look at this, keeping the same example of ED50 to ETRS89, let's consider the far-west of Europe (Spain and Portugal). Here, the relevant authorities have produced three distinct conversions, each for a different area. They are shown below in orange:







Even after deduplication, there are over 3000 distinct geographic extents required to support the full range of PHPCoord's conversion abilities. Because borders are rarely straight lines, the full set of extent data for each and every coordinate system supported by PHPCoord would be over 100Mb of polygon data. That is far, far too much data to ask each and every library user to download and incorporate into their application.

Grids

For more modern coordinate systems it is becoming standard for mapping agencies to go beyond simply providing tailored parameters for broad regions or states within their territory and to provide detailed adjustments using a grid. For instance in New Zealand a 20km×20km grid provided by LINZ can be used to make significantly more precise conversions between NZGD1949 and NZGD2000. Using the grid provides for typical accuracy of $\pm$0.2m, compared to a 4m accuracy from the alternative published transformation. For obvious reasons these grid files can also be quite large, and therefore the same concerns about packaging them apply.

"Out of the box"

The core PHPCoord package attempts to strike a pragmatic balance between accuracy and download size. It does not provide access to any grid-based corrections, and it uses simple bounding boxes (the green lines) as extent data rather than the detailed orange polygons.

As is obvious from looking at the Spain/Portugal images though, the areas enclosed by the green boxes have areas of overlap. In fact there are areas of north-east Portugal that are actually encompassed by all 3! If a coordinate is located within one of these overlap areas, then each of those 3 possible conversions is necessarily considered equally valid, and which one is ultimately utilised is undefined. The difference in resulting coordinate from any use of the "wrong" formula is likely to be very small (perhaps a few metres).

Note: This particular example was European, but "wrong" conversions can be picked wherever there are multiple extents for a given pair of coordinate systems. For example NAD27/83 conversions in North America, or SAD69 conversions in South America can be similarly affected.

Add-on datapacks

Not every user will consider the above tradeoff to be desirable, preferring instead to have the highest-accuracy conversions possible even at the cost of increased disk space.

PHPCoord supports this mode of operation via the use of optional add-on "datapacks". These are additional Composer packages (8 available), each corresponding to a different region of the world:

- `php-coord/datapack-africa`
- `php-coord/datapack-antarctic`
- `php-coord/datapack-arctic`
- `php-coord/datapack-asia`
- `php-coord/datapack-europe`
- `php-coord/datapack-northamerica`
- `php-coord/datapack-oceania`
- `php-coord/datapack-southamerica`

Installing them provides access to the full-fidelity polygons for the relevant area of the world (at a scale of approx 1:15000000) and also any applicable grid files allowing PHPCoord to do the best possible job.

No configuration is necessary once installed.

1.4.2 The hard way

Each type of `Point` has methods you can invoke to run well-known algorithmic conversions on its coordinates.

They are listed in detail on the following pages.

Tip: The first parameter of every method is always a `CoordinateReferenceSystem` object representing the target CRS. For guidance on remaining parameters, please see a textbook as explaining them is far outside the scope of this documentation.

1.5 Distance calculations

PHPCoord can calculate the distance between two `Points` via the `calculateDistance()` method.

```
public function calculateDistance(
    Point $to,
): Length
```

- The distance between two `ProjectedPoints` is calculated via Pythagoras

- The distance between two `GeographicPoints` or two `GeocentricPoints` is calculated via Vincenty's formula
- The distance between two `VerticalPoints` is calculated as simple difference

Example

```
$from = GeographicPoint::create(...);
$to = GeographicPoint::create(...);
$distance = $from->calculateDistance($to);
```

1.6 Built in coordinate systems

Note: In ISO 19111 terminology, what most people refer to as a *Coordinate System* is actually called a *Coordinate Reference System* (or *CRS* for short), with the term *Coordinate System* being used to refer to the *axes used*. PHPCoord's actual code uses the ISO naming system, although this documentation uses the more common version.

Tip: A constant has been defined for each and every built in CRS, with supporting docblocks that match the contents of the following pages. These should be searchable/available for autocomplete from inside your favourite IDE.

Tip: You can also access the list of supported CRSs at runtime using `CoordinateReferenceSystem::getSupportedSRIDs()` or `CoordinateReferenceSystem::getSupportedSRIDsWithHelp()`

1.6.1 Geocentric

Tip: You can access the list of supported geocentric CRSs at runtime using `Geocentric::getSupportedSRIDs()` or `Geocentric::getSupportedSRIDsWithHelp()`
